Very energetic astrophysical events are required to accelerate cosmic rays to above $10^{18}$ eV. Gamma-ray bursts (GRBs) have been proposed as possible candidate sources. In the GRB fireball model, cosmic ray acceleration should be accompanied by neutrinos produced in the decay of charged pions created in interactions between the high-energy cosmic-ray protons and gamma-rays. Previous searches for such neutrinos found none, but the constraints were weak as the sensitivity was at best approximately equal to the predicted flux. Here we report an upper limit on the flux of energetic neutrinos associated with gamma-ray bursts that is at least a factor of 3.7 below the predictions. This implies that GRBs are not the only sources of cosmic rays with energies $>10^{18}$ eV or that the efficiency of neutrino production is much lower than has been predicted.
process $p + \gamma \rightarrow \Delta^+ \rightarrow n + \pi^+$. When these pions decay via $\pi^+ \rightarrow \mu^+ + \nu_\mu$, and $\mu^+ \rightarrow e^+ + \nu_e + \bar{\nu}_\mu$, they produce a flux of high-energy muon and electron neutrinos, coincident with the gamma rays, and peaking at energies of several hundred TeV (Suppl. Fig. [1]). Such a flux should be detectable using km$^3$-scale instruments like the IceCube neutrino telescope (Suppl. Fig. [1]). Due to maximal mixing between muon and tau neutrinos, neutrinos from pion decay in and around GRBs will arrive at Earth in an equal mixture of flavors. We focus here only on muons produced in $\nu_\mu$ charged-current interactions. As the downgoing cosmic ray muon background presents challenges for the identification of neutrino-induced muons, we achieve our highest sensitivity for upgoing (northern hemisphere) neutrinos. However, the tight constraint of spatial and temporal coincidence with a gamma-ray burst allows some sensitivity even in the southern sky. One of the two analyses presented here therefore includes southern-hemisphere gamma-ray bursts during the 59-string IceCube run.

The results presented here were obtained while IceCube was under construction using the 40- and 59-string configurations of the detector, which took data from April 2008 to May 2009 and from May 2009 until May 2010, respectively. During the 59-string data taking period, 190 GRBs were observed and reported via the GRB Coordinates Network with 105 in the northern sky. Of those GRBs, 9 were not included in our catalog due to detector downtime associated with construction and calibration. Two additional GRBs were included from test runs before the start of the official 59-string run. 117 northern-sky GRBs were included from the 40-string period to compute the final combined result. GRB positions were taken from the satellite with the smallest reported error, which is typically smaller than the IceCube resolution. The GRB gamma-emission start ($T_{\text{start}}$) and stop ($T_{\text{stop}}$) times were taken by finding the earliest and latest time reported for gamma emission.

As in our previous study, we conducted two analyses of the IceCube data. In a model-dependent search, we examine data during the period of gamma emission reported by any satellite for neutrinos with the energy spectrum predicted from the gamma-ray spectra of individual GRBs. The model-independent analysis searches more generically for neutrinos on wider time scales, up to the limit of sensitivity to small numbers of events at $\pm 1$ day, or with different spectra. Both analyses follow the methods used in our previous work, with the exception of slightly changed event selection and the addition of the southern hemisphere to the model-independent search. Due to the large background of down-going muons from the southern sky, the southern hemisphere analysis is sensitive mainly to higher energy events (Suppl. Fig. [3]). Systematic uncertainties from detector effects have been included in the reported limits from both analyses and were estimated by varying the simulated detector response and recomputing the limit, with the dominant factor the efficiency of the detector’s optical sensors.

In the 59-string portion of the model-dependent analysis, no events were found to be both on-source and on time (within 10$^\circ$ of a GRB and between $T_{\text{start}}$ and $T_{\text{stop}}$). From the individual burst spectra, with the ratio of energy in protons vs. electrons $\epsilon_p/\epsilon_e = 10$ (Ref. [6], 5.2 signal events were predicted from the combined 2-year dataset and a final upper limit (90% confidence) of 0.47 times the predicted flux can be set (Fig. [1]). This corresponds to a 90% upper limit on $\epsilon_p/\epsilon_e$ of 4.7, with other parameters held fixed, and includes a 6% systematic uncertainty from detector effects.

In the model-independent analysis, two candidate events were observed at low significance, one 30 seconds after GRB 091026A (Event 1) and another 14 hours before GRB 091230A (most theories predict neutrinos within a few minutes of the burst). Subsequent examination showed they had both triggered several tanks in the IceTop surface air shower array, and are thus very likely muons from cosmic ray air showers. In Fig. [2] are shown limits from this analysis on the normalization of $E^{-2}$ muon neutrino fluxes at Earth as a function of the size of the time window $|\Delta t|$, the difference between the neutrino arrival time and the first reported satellite trigger.
Muon neutrino events

FIG. 2. Upper limits on \(E^{-2}\) power-law muon neutrino fluxes. Limits were calculated using the Feldman-Cousins method [24] from the results of the model-independent analysis. The left y-axis shows the total number of expected \(\nu_e\) events while the right-hand vertical axis (\(F_{\nu}\)) is the same as in Fig. 1. A time window of \(\Delta t\) implies observed events arriving between \(t\) seconds before the burst and \(t\) afterward. The variation of the upper limit with \(\Delta t\) reflects statistical fluctuations in the observed background rate, as well as the presence of individual events of varying quality. The event at 30 seconds (Event 1) is consistent with background and believed to be a cosmic-ray air shower.

The event at 30 seconds (Event 1) is consistent with background and believed to be a cosmic-ray air shower.

As a follow up to the model-dependent search, the limit from this analysis on the average individual burst spectra [25] during the time window corresponding to the median duration of the bursts in the sample (28 seconds) was 0.24 times the predicted flux, reflecting the added sensitivity of the larger burst catalog.

Assuming that the GRBs in our catalog are a representative sample of a total of 667 per year [26], we can scale the emission from our catalog to the emission of all GRBs. The resulting limits can then be compared to the expected neutrino rates from models that assume that GRBs are the main sources of ultra high energy cosmic rays [27–29], with sampling biases of the same order as model uncertainties in the flux predictions [27–29]. Limits from the model-independent analysis on fluxes of this type are shown in Fig. 3.

These limits exclude all tested models [30,31] with their standard parameters and uncertainties on those parameters (Figs. 1, 3). The models are different formulations of the same fireball phenomenology, producing neutrinos at proton-photon (pγ) interactions in internal shocks. The remaining parameter spaces available to each therefore have similar characteristics: either a low density of high-energy protons, below that required to explain the cosmic rays, or a low efficiency of neutrino production.

In the GRB fireball, protons are believed to be accelerated stochastically in collisions of internal shocks in the expanding GRB. The neutrino flux is proportional to the rate of pγ interactions, and so to the proton content of the burst by a model-dependent factor. Assuming a model-dependent proton ejection efficiency, the proton content can in turn be related to the measured flux of high-energy cosmic rays if GRBs are the cosmic ray sources. Limits on the neutrino flux for cosmic ray normalized models are shown in Fig. 3. Each model prediction has been normalized to a value consistent with the observed ultra high-energy cosmic ray flux. The proton density can also be expressed as a fraction of the observed burst energy, 

\[ \epsilon_b \propto \frac{E}{\pi} \]

or by increasing the bulk Lorentz factor Γ [32]. Error bars on model predictions are approximate and were taken either from the original papers, where included, or from the best-available source in the literature [33]. Otherwise, the errors are due to uncertainties in \(f_p\) and in fits to the cosmic-ray spectrum. Waxman-Bahcall [34] and Rachen [35] fluxes were calculated using a cosmic ray density of \(1.5 \times 10^{44} \text{ erg Mpc}^{-3} \text{ yr}^{-1}\), with \(3 \times 10^{44}\) the central value [36].

FIG. 3. Compatibility of cosmic-ray flux based models with observations. Shown are the allowed values of neutrino flux vs. the neutrino break energy \(\epsilon_b\) in comparison to model predictions with estimated uncertainties. Data were taken from the model-independent analysis from the time window corresponding to the median duration of the GRBs in our catalog (\(\Delta t = 28\) seconds). Spectra are represented here as broken power laws \(\phi_{\nu} \propto (E^{-\epsilon_b} \cdot \epsilon_b < \epsilon_b; E^{-2}, E > \epsilon_b)\) with a break energy \(\epsilon_b\) corresponding to the \(\Delta\) resonance in the frame of the shock. The muon flux in IceCube is dominated by neutrinos with energies around the first break \(\epsilon_b\). As such, the upper break, due to synchrotron losses of \(\pi^+\), has been neglected here, as its presence or absence does not contribute significantly to the muon flux and thus does not have a significant effect on the presented limits. \(\epsilon_b\) is related to the bulk Lorentz factor Γ (\(\epsilon_b \propto \Gamma^2\)); all of the models shown assume Γ < 300. The value of Γ corresponding to 107 GeV is > 1000 for all models. Vertical axes are related to the accelerated proton flux by the model-dependent constant of proportionality \(f_p\). Of models assuming a neutron-decay origin of cosmic rays (Rachen [37] and Ahlers [38]) \(f_p\) is independent of Γ; for others (Waxman-Bahcall [34]) \(f_p \propto \Gamma^{-4}\). Error bars on model predictions are approximate and were taken either from the original papers, where included, or from the best-available source in the literature [33].

An alternative is to reduce the neutrino production efficiency, for example by modifying the physics included in the predictions [39].
The general conclusion is the same for all the versions of fireball phenomenology we have considered here: either the proton density in gamma ray burst fireballs is substantially below the level required to explain the highest energy cosmic rays or the physics in gamma ray burst shocks is significantly different from that included in current models. In either case, our current theories of cosmic ray and neutrino production in gamma ray bursts will have to be revisited.

AUTHOR CONTRIBUTIONS

The IceCube observatory has been designed and constructed by the IceCube Collaboration and the IceCube Project. It is operated by the IceCube Collaboration, who set science goals. Data processing and calibration, Monte Carlo simulations of the detector and of theoretical models, and data analyses are performed by a large number of IceCube members who also discuss and approve the scientific results. This manuscript was written by P.R. and N.W. and subjected to an internal collaboration-wide review process. All authors approved the final version of the manuscript.

SUPPL. FIG. 1. The IceCube neutrino observatory. The IceCube detector instruments a volume of 1 km$^3$ of glacial ice at the South Pole, sensitive to neutrinos of TeV and higher energy (Suppl. Fig. 2). Neutrinos are detected by observing Cherenkov light emitted by secondary charged particles produced in neutrino-nucleon interactions, and their arrival direction is obtained from the timing pattern of the detected light. The finished detector is composed of 5160 digital optical modules (DOMs), each containing a 10-inch photomultiplier, with 60 placed at depths between 1450 and 2450 m on each of 86 vertical strings. IceCube is complemented by a surface air shower array called IceTop, with two tanks located above each of the IceCube strings. The colors at the top indicate the detector at various stages of deployment. IceCube achieves its best angular resolution for muons produced in $\nu_\mu$ charged-current interactions (0.6° for $E_\nu \gtrsim 100$ TeV). Combined with the increased detector effective volume afforded by the long distances traveled by the secondary muons, such events usually provide the highest sensitivity for searches for neutrino point sources.

GRB CATALOG

The GRB catalog used in this analysis was synthesized from GCN notices and can be obtained using the GRBweb database available at [http://grbweb.icecube.wisc.edu/](http://grbweb.icecube.wisc.edu/). IceCube-40 operated by April 5, 2008 until May 20, 2009 and IceCube-59 operated from May 21, 2009 until May 31, 2010. GRB090422 and GRB090423, though before the official 59-string start date, occurred during test runs of the 59-string detector and so are included in the 59-string catalog.

SUPPL. FIG. 2. Effective area of the IceCube neutrino telescope using the event selections of the model-dependent and model-independent analyses, averaging over the 40- and 59-string detector configurations and zenith angles according to the distribution of bursts in the catalog. The effective area of the model-independent event selection is in general somewhat larger, due to using a weight scheme instead of hard cuts – however, the extra events so included are typically low quality and so have low weights when computing final results. The model-independent average effective area includes the southern hemisphere for the 59-string portion of the analysis (Suppl. Fig. 3).

EFFECTIVE AREAS

The detector effective areas (Suppl. Figs. 2, 3) can be used to estimate the detector response for an arbitrary neutrino flux. Convolution of a flux with the effective area will give the expected event rate in IceCube. Presented effective areas are the average of the effective areas for muon neutrinos and muon antineutrinos and correspond to the expectation value of the detector effective area under variations to account for systematic uncertainties in the detector simulation. The increase in effective area between the 40- and 59-string detector configurations is due to the 50% increase in geometrical area of the detector, a more favorable detector geometry, and improvements in the event selection and reconstruction techniques (Suppl. Fig. 4). Data files containing all the effective areas plotted here are included in the supplementary information (Suppl. Tables 1-6).

COMBINATION OF DATASETS

The results presented use a combination of the IceCube 40- and 59-string datasets. In both analyses, all GRBs were individually simulated and this simulation was applied to the detector running at the time of the GRB. The simulated events from the full GRB catalog were treated as a combined dataset, which was then compared to the combined result from both detector configurations. Sys-
SUPPL. FIG. 3. Average effective area of the IceCube neutrino telescope in its 59-string configuration to fluxes of muon neutrinos from the northern and southern hemispheres, using the event selection from the model-independent analysis. At low energies, the ability to use the Earth to filter out neutrinos from cosmic ray air showers reduces backgrounds and improves the sensitivity of the detector to neutrinos from the northern sky. As the neutrino energy increases, so does the neutrino-nucleon cross-section, increasing the neutrino interaction probability and the chances of a detection in IceCube. At very high energies, backgrounds from cosmic-ray muons are substantially reduced and the neutrino-nucleon cross-section becomes large enough that neutrinos from the northern hemisphere will be absorbed in the Earth before reaching the detector, making the southern hemisphere the region of highest sensitivity for $E_\nu \gtrsim 1$ PeV. Note that the effective area is not a direct estimate of the sensitivity, due to variable backgrounds as a function of zenith angle and energy. In general, backgrounds are highest in the southern hemisphere and at low energies.

SUPPL. FIG. 4. Comparison of IceCube effective area between the 40- and 59-string detectors in the northern hemisphere using the model-independent event selection. The increase in effective area is related to the increased geometric area of the detector, as well as to improved event selection and reconstruction techniques. Low-energy sensitivity was especially enhanced as a result of a more favorable detector geometry and the deployment of the first of the strings of the Deep Core subdetector. As a result, the integrated effective area of the 59-string detector for this analysis is more than 1.5 times that of the 40-string detector.
